Notes
Association of matrilin-3 polymorphisms with spinal disc degeneration and osteoarthritis of the first carpometacarpal joint of the hand

J L Min, I Meulenbelt, N Riyazi, M Kloppenburg, J J Houwing-Duistermaat, A B Seymour, C M van Duijn, P E Slagboom

Background: Seven polymorphisms in the matrilin-3 (MATN3) gene were previously tested for genetic association with hand osteoarthritis in an Icelandic cohort. One of the variants, involving a conserved amino acid substitution (T303M; SNP5), was related to idiopathic hand osteoarthritis.

Objectives: To investigate SNP5 and two other promising polymorphisms (rs2242190; SNP3, rs8176070; SNP6) for association with radiographic and symptomatic hand osteoarthritis phenotypes, as well as other heritable phenotypes.

Methods: Polymorphisms were examined in two distinct cohorts of subjects: a population based sample from the Rotterdam study (n = 809), and affected siblings from the Genetics, Osteoarthrosis and Progression (GARP) study (n = 382).

Results: The originally described association of T303M with the hand osteoarthritis phenotype was not observed in the populations studied. In the Rotterdam sample, however, carrying the T allele of T303M conferred an odds ratio of 2.9 (95% confidence interval (CI), 1.2 to 7.3; p = 0.02) for spinal disc degeneration. In the GARP study, carriers of the A allele of SNP6 had an odds ratio of 2.0 (95% CI, 1.3 to 3.1, p = 0.004) for osteoarthritis of the first carpometacarpal joint (CMC1) as compared with the Rotterdam sample as a control group. Subsequent haplotype analysis showed that a common haplotype, containing the risk allele of SNP6, conferred a significant risk in sibling pairs with CMC1 osteoarthritis (odds ratio = 1.7 (95% CI, 1.1 to 2.7, p = 0.02)).

Conclusions: These associations suggest that the MATN3 region also determines susceptibility to spinal disc degeneration and CMC1 osteoarthritis.

Osteoarthritis is a common age related degenerative disease of the joints characterised by gradual loss of articular cartilage. Twin and sibling pair studies have shown that genetic factors play a substantial role in the aetiology of osteoarthritis. Heritabilities range between 30% and 80%, depending on sex and the specific joint site (spine, hand, hip, knee, or generalised) involved. Several genome-wide scans, based on a variety of joint site (spine, hand, hip, knee, or generalised) definitions of osteoarthritis, have been undertaken and have revealed positive linkage areas, some of which contain candidate genes for the susceptibility to osteoarthritis.

A scan of 329 Icelandic families with idiopathic hand osteoarthritis (involvement of either or both the distal interphalangeal (DIP) and first carpometacarpal (CMC1) joints) highlighted evidence for linkage on chromosome 2p, 4q, 3p. For the chromosome 2 loci, high LOD (log of odds) scores were reached for patients with affected CMC1 joints and for those with osteoarthritis in both CMC1 and DIP joints. Recently, the genome scan by Hunter et al revealed separate chromosomal regions for osteoarthritis of CMC1 and DIP joints, again by using a joint specific hand approach. Taken together, these studies indicate that osteoarthritis in different hand joints should be analysed as separate entities.

The chromosome 2p locus in the Icelandic study coincides with the matrilin-3 gene (MATN3) encoding a non-collagenous extracellular oligomeric matrix protein. Mutations in this gene have previously been shown to cause different forms of multiple epiphyseal dysplasia. This disease is characterised by generalised dysplasia of epiphyses followed by early onset osteoarthritis, mainly affecting the knee and hip joints.

Stefansson et al explored seven polymorphisms (SNP1-6 and Indel1, nomenclature as in their paper) at the MATN3 locus and found an association with the T allele of a conserved amino acid substitution (T303M; SNP5) among patients with either idiopathic hand osteoarthritis, DIP osteoarthritis, or CMC1 osteoarthritis (0.01) as compared with the Icelandic population (0.005). In these patients, a moderately insignificant effect was observed for the A allele of SNP6 (rs8176070). The question arises as to whether variants of a gene that is widely expressed in developing cartilage and bone, and highly upregulated in human osteoarthritis cartilage compared with healthy cartilage, increases the risk of hand osteoarthritis only or whether it is also involved in other heritable osteoarthritis phenotypes. In this report, we therefore investigated the findings of SNP5 in relation to hand osteoarthritis in a population based sample of the Rotterdam study and in an osteoarthritis affected sibling pair study (the Genetics, Osteoarthrosis and Progression (GARP) study). We further examined whether SNP5 and two other promising MATN3 polymorphisms (rs2242190; SNP3 and rs8176070; SNP6) of the Icelandic report were associated with radiographic and symptomatic osteoarthritis phenotypes also at other joint sites in the...
Rotterdam sample or the GARP study. Finally, we explored the initial associations of separate single nucleotide polymorphisms (SNPs) at this locus by haplotype analysis.

METHODS
The Rotterdam study
The Rotterdam study, which comprises 7983 white participants, is a prospective, population based cohort study of the determinants and prognosis of chronic diseases in the elderly.14

The medical ethics committee of the Erasmus University Medical School approved the study, and informed consent was obtained from all subjects. In a random sample of unrelated subjects aged 55 to 65 years (n = 809), radiographs were scored for the presence of radiographic osteoarthritis (ROA) of the knees, hips,15 the hands, and thoracolumbar spine.16 All radiographs were scored according to the Kellgren/Lawrence grading system (grades 0 to 4)17 by two independent readers, blinded to all other data of the participants. After each set of about 150 radiographs the scores of the two readers were evaluated. Whenever the scores differed by 2 or more points, or was 2 for one reader but 1 for the other, a consensus score was agreed upon. ROA of the knee was only assessed in the tibiofemoral joint. ROA of the spine is confined to the lateral radiographs of the spine that were available. Instead, we assessed disc degeneration of the spine, according to a Kellgren/Lawrence grading scale,17 at three levels—that is, thoracic (T4 to Th12), lumbar (L1 to L4 or L5), and lumbosacral (L3-S1 or L5-L6). Definite ROA at a particular joint site was defined as a Kellgren/Lawrence score of ≥2.17

In the Rotterdam sample, hand ROA at one or two hand joint groups (56% and 37%, respectively) or spinal disc degeneration at one level (61%) is already very prevalent and is likely to be a part of the normal wear and tear process. To enrich the sample for subjects who may be genetically predisposed to osteoarthritis, we divided the subjects into quartiles of the sum score of affected hand joint groups or spinal disc levels, respectively, based on the distribution of the complete Rotterdam sample (n = 809). Subjects with hand ROA in three or more hand joint groups (the right and left hands were considered separately), representing the highest quartile of the population, were compared with subjects with hand ROA in fewer than three hand joint groups. Subjects affected by spinal disc degeneration at two or more disc levels (25% cut off value) were compared with subjects with one or no disc levels affected.

In order to confirm previous findings, the following subanalyses for hand phenotypes were conducted. Subjects with one or more DIP joint affected on each hand were compared with subjects with fewer than one DIP joint affected on each hand; subjects with CMC1 ROA in one or more CMC1 joints affected were compared with subjects with fewer than one CMC1 joint affected. In our analysis, we compared each specific case group with a specific control group, which comprises the complete Rotterdam sample, excluding that specific case group. These control groups are more robust than the rare group that is completely negative for ROA in all joint groups investigated (17%).

The GARP study
The ongoing GARP study, which consists of white sibling pairs of Dutch origin affected predominantly by symptomatic osteoarthritis at multiple sites, is aimed at identifying determinants of osteoarthritis susceptibility and progression.18 Probands (ages 40–70 years) and their siblings had osteoarthritis at multiple joint sites of the hand or in ≥2 of the following joint sites (hand, spine (cervical or lumbar), knee or hip).18

Subjects with symptomatic osteoarthritis (as defined below) at just one joint site were required to have structural abnormalities at least one other joint site, defined by the presence of ROA in any of the four joints, or the presence of ≥2 Heberden’s nodes, Bouchard’s nodes, or squaring of at least one CMC1 joint on physical examination. Symptomatic osteoarthritis in the knee and hip was defined according to the American College of Rheumatology (ACR) recommendations for knee and hip osteoarthritis.19 20 Knee osteoarthritis was defined as pain or stiffness for most days of the preceding month and osteophytes at the joint margins of the tibiofemoral joint (x ray spurs).

Hip osteoarthritis was defined as pain or stiffness in the groin and hip region on most days of the preceding month in addition to femoral or acetabular osteophytes or axial joint space narrowing on radiography. Prosthetic joints in the hips or knees as a result of end stage osteoarthritis were defined as osteoarthritis in that particular joint. Spine osteoarthritis (cervical and lumbar) was defined as pain or stiffness in the spine on most days of the preceding month, in addition to a Kellgren/Lawrence score of 2 in at least one disc or one apophyseal joint.

Osteoarthritis in hand joints was defined according to the ACR criteria21 as pain or stiffness on most days of the preceding month, in addition to three of the following four criteria: bony swelling of two or more of the 10 selected joints (bilateral DIP joints 2–3, bilateral PIP joints 2–3, and CMC1 joints), bony swelling of two or more DIP joints, fewer than three swollen MCP joints, and deformity of at least one of the 10 selected joints.

Intrareader variability for the different joint sites, scored by the Kellgren/Lawrence method, was assessed as follows: the intraclass correlation coefficient (ICC, with 95% confidence interval) was for the hand, 0.95 (0.92 to 0.96); for the knees (tibiofemoral), 0.92 (0.86 to 0.96); for the hips, 0.95 (0.92 to 0.98); for the cervical spine (apophyseal and disc), 0.71 (0.52 to 0.84); and for the lumbar spine (apophyseal and disc), 0.67 (0.46 to 0.81). Intrareader variability was based on an examination of 40 radiographs that were selected randomly throughout the duration of the study period and were blinded for any patient characteristics.

To replicate previous findings, a subanalysis was carried out for osteoarthritis in the different hand joints. DIP or CMC1 osteoarthritis cases were defined by pain or stiffness at a CMC1 or a DIP joint in addition to a Kellgren/Lawrence score of at least 2 in a CMC1 or DIP joint. From all CMC1 or DIP cases in the GARP study, 86% and 75%, respectively, met the Icelandic criteria for these phenotypes. In this analysis, sibling pairs of the GARP study were compared with the complete sample of the Rotterdam study as control group, which is called “the Rotterdam sample” and represents the normal population.

Statistical analysis
Differences in allele frequencies between case and control groups from the Rotterdam study were calculated by Pearson’s χ² test or Fisher’s exact test for rare alleles. For the distribution of genotypes, the Hardy–Weinberg equilibrium (HWE) was tested by using the HWE program of LINKUTIL (http://linkage.rockefeller.edu/ott/linkutil.htm) or

BMI, body mass index; CMC1, first carpometacarpal joint; DD, spinal disc degeneration; DIP, distal interphalangeal joint; GARP, Genetics, Osteoarthritis and Progression study; OA, osteoarthritis; ROA, radiographic osteoarthritis.
genotyped by restriction fragment length analysis using digestions of 5 μl PCR product with 0.1 μl AlIII (New England Biolabs, Beverley, Massachusetts, USA) or 0.1 μl PciI (New England Biolabs) in a final volume of 15 μl, respectively. Digestion products were electrophoresed through 1.5% agarose gels stained with ethidium bromide. Six subjects who had the rare T allele of SNP5 were sequenced to confirm the genotype of SNP6 (TG or TA).

The remaining polymorphisms were genotyped by mass spectrometry (homogeneous Mass ARRAY system: Sequenom Inc, San Diego, California, USA), using standard conditions. Genotypes were analysed by using Genotyper 3.0 software (Sequenom Inc).

RESULTS

Characteristics of subjects from both the Rotterdam sample and the GARP study are shown in table 1. In the Rotterdam study, each specific case group was compared to a specific control group, while specific control group as control group may be conservative for the normal population. Using a population complete Rotterdam sample as control group (n = 809), we had anticipated that SNP5 would be associated with hand osteoarthritis phenotypes. In the Rotterdam sample, association analysis was carried out for SNP3, SNP5, and SNP6 (nomenclature as described by Stefansson et al) in different case and control groups, as previously defined (table 2). In view of previous observations, we had anticipated that SNP5 would be associated with hand osteoarthritis phenotypes. In the Rotterdam sample, no significant differences between case groups with hand ROA, CMC1 ROA, or DIP ROA and their control groups were observed (not shown). The absolute values of these variables were similar. BMI, age, and sex were added as covariates in all logistic regression analyses to account for these differences.

Association analysis of SNP3, SNP5, and SNP6 in the Rotterdam sample

In the Rotterdam sample, association analysis was carried out for SNP3, SNP5, and SNP6 (nomenclature as described by Stefansson et al) in different case and control groups, as previously defined (table 2). In view of previous observations, we had anticipated that SNP5 would be associated with hand osteoarthritis phenotypes. In the Rotterdam sample, no significant differences between case groups with hand ROA, CMC1 ROA, or DIP ROA and their control groups were observed. The frequency of the T allele of this SNP5, however, was significantly increased in subjects with spinal disc degeneration at two or more levels (0.031, p = 0.007) compared with the controls (0.009). Carriers of this T allele had an increased risk of 2.9 (95% CI, 1.2 to 7.3; p = 0.02) of having spinal disc degeneration at two or more levels. Further stratification for sex did not reveal any sex specific associations (data not shown).

We estimated haplotype frequencies and effects among subjects with spinal disc degeneration at two or more levels and their controls. In the whole Rotterdam sample, we

observed five haplotypes, represented by SNP3, SNP5, and SNP6, respectively (table 4). The frequencies of the A-T-G haplotype, containing the risk T allele of SNP5, showed identical frequencies to the T allele of SNP5 alone.

**Association analysis of SNP3, SNP5, and SNP6 in the GARP study**

In the GARP study, we investigated the association of SNP3, SNP5, and SNP6 in relation to symptomatic hand osteoarthritis phenotypes (hand osteoarthritis, CMC1 osteoarthritis, and DIP osteoarthritis) and to familial osteoarthritis at multiple joint sites (table 3). Because no significant differences were found between the case and control groups of the Rotterdam sample for these phenotypes, the total Rotterdam sample was compared to the cases of the GARP study. We did not observe a significant relation of either SNP3 or SNP5 with any of the definitions of spinal disc degeneration (data not shown), osteoarthritis in the hand, or osteoarthritis at multiple joint sites. However, the A allele of SNP6 was significantly increased in subjects with osteoarthritis of the CMC1 joint (0.29, p = 0.01) compared with the Rotterdam sample as the control group (0.21). Among carriers of one or more risk alleles, this A allele conferred an adjusted OR of 2.0 (95% CI, 1.3 to 3.1; p = 0.004) for CMC1 osteoarthritis. Stratification for women only revealed an adjusted OR of 2.0 (95% CI, 1.3 to 3.1; p = 0.004) for carriers of one or more risk alleles, this A allele conferred a significant and increased risk of 1.7 (95% CI, 1.1 to 2.1; p = 0.02) in all sibling pairs with CMC1 osteoarthritis compared with the Rotterdam sample as control group.

To further delineate this possible risk haplotype, we included two htsSNPs in the haplotype analysis. These haplotypes were represented by the five polymorphisms in the following order: rs1191818 (T>C), SNP3 (G>A), SNP5 (C>T), SNP6 (G>A), and rs3731663 (C>T). Haplotype analysis of these five SNPs showed that the common C-A-C-A-T haplotype, encompassing the A-C-A haplotype, conferred a significant and increased risk of 1.7 (95% CI, 1.1 to 2.7; p = 0.02) in all sibling pairs with CMC1 osteoarthritis, and 2.1 (95% CI, 1.3 to 3.5; p = 0.004) in all sibling pairs with CMC1 osteoarthritis, stratified for women only.

**DISCUSSION**

Our results indicate that SNP5 of the MATN3 gene, previously associated with idiopathic hand osteoarthritis in the Icelandic population, is involved in other heritable osteoarthritis phenotypes such as spinal disc degeneration. Carriers of this T allele showed an increased risk of 2.9 (95% CI, 1.2 to 7.3, p = 0.02) of having disc degeneration at two or more levels in the population based Rotterdam sample. In the study by Stefansson et al, no phenotypic data on spinal disc degeneration appeared to be available. We did not find any significant association of SNP5 with similar clinical hand osteoarthritis, CMC1 osteoarthritis, or DIP osteoarthritis phenotypes as described in the Icelandic study, or with the radiographic hand phenotypes defined in the current study. Observations in the study by Stefansson et al suggested that the T allele of SNP5 might be important as the nucleotide change predicts a very conserved amino acid substitution. We observed that the frequencies of the A-T-G haplotype are identical to the frequencies of the T allele of SNP5 alone.

Although a possible genetic relation between generalised ROA and spinal disc degeneration was suggested, there is no consensus as to whether spinal disc degeneration constitutes a form of osteoarthritis or is a distinct joint disease. The lack of association of SNP5 with spinal disc degeneration in the GARP study may be because only a few subjects in the GARP study carried the T allele of SNP5. Moreover, spinal disc degeneration in these selected sibling pairs might be part of a specific generalised osteoarthritis phenotype.

Matrilins mediate interactions with cartilage oligomeric matrix protein, aggrecan, collagen type II, and collagen type IX, presumably acting as adaptors connecting macromolecular networks. Although the precise function of matrilin-3 is still unknown, variants in this gene may reduce its stabilising role in the extracellular cartilage matrix.

Mutations in the region encoding the von Willebrand domain (vWFA) of MATN3 cause multiple epiphyseal dysplasia, mainly in the knee and hip joints. In addition, a recent paper reported a homozygous mutation (C304S) located in the first epidermal growth factor-like domain, lying in the immediate vicinity of SNP5, resulting in a novel form of spondylo-epimetaphyseal dysplasia. Recently, Otten et al have attempted to elucidate the pathogenic mechanism of these matrilin-3 mutations at the cellular level. In this study, two point mutations causing chondrodysplasia (R121W and C304S) and SNP5 were introduced, and the corresponding proteins were expressed in primary articular chondrocytes. In contrast to the chondrodysplasia mutations, SNP5 mutants were expressed, processed, secreted, and incorporated in an extracellular network in a manner similar to the wild type matrilin-3. These results, and the small effect sizes in both the Icelandic and our study, suggest that SNP5 (T303M) results only in

subtle structural and functional consequences or is not responsible for the observed effect.

As compared with the Icelandic study, we observed a two to three times higher allele frequency of the T allele of SNP5, especially in our control groups consisting of subjects from the population based Rotterdam sample. This may reflect differences in genetic background. However, the allele frequencies of SNP3 and SNP6 are similar in our studies and the Icelandic study. The failure of replication of the previous findings in the Icelandic study may underlie in this frequency difference of SNPs in the control group. Therefore, the allele frequency of SNP5 should be checked in other populations.

In combining the Rotterdam study and the GARP study, we have the opportunity to investigate the contribution of gene variants to the susceptibility of osteoarthritis in four joint groups (hip, hand, knee, and spinal disc degeneration). The Rotterdam study includes radiographic osteoarthritis phenotypes irrespective of symptoms; the GARP study represents familial symptomatic osteoarthritis at multiple sites. The lack of association of SNP5 with hand osteoarthritis in our studies may be explained if this variant is associated specifically with symptomatic osteoarthritis in the hands. We have limited information on symptomatic osteoarthritis characteristics in the Rotterdam sample and we have a selection for osteoarthritis at multiple joint sites in the GARP study. Consequently, we have a small number of SNP5 carriers in the GARP study.

In the GARP study, however, SNP6 of the MATN3 gene indicated an association for osteoarthritis at the CMC1 joint. Carriers of the A allele among the affected siblings had a significantly increased risk of 2.0 (95% CI, 1.3 to 3.1; \( p = 0.004 \)) of having CMC1 osteoarthritis. An increased frequency of the A allele of SNP6 in subjects with CMC1 osteoarthritis and the risk haplotype A-C-A for hand osteoarthritis was also observed in the study by Stefansson et al; however, it appeared to be non-significant.\(^4\) In the Rotterdam study, we did not have symptomatic CM1C data available to replicate this association with SNP6. However, the function of SNP6 is unknown and it could be that SNP6 has no functional consequences but is in linkage disequilibrium with the causal variant.

Our studies, therefore, did allow us to detect associations of SNP6 with symptomatic CMC1 osteoarthritis and SNP5 with spinal disc degeneration, which emphasise that osteoarthritis is heterogeneous and multifactorial in its aetiology. As in many genetic association studies, we cannot exclude the possibility of false positive findings caused by multiple comparisons. At this stage we conclude that we did confirm previous results indicating the relevance of the MATN3 locus for osteoarthritis.

We observed a relatively high frequency of the A-C-A haplotype with a moderate risk for CMC1 osteoarthritis. However, the three polymorphisms examined represent only a limited sample of the known haplotypes of the MATN3 region. Therefore, we investigated whether a more extended haplotype using hSNPs delineated a more specific haplotype conferring a higher risk of CMC1 osteoarthritis. Although these hSNPs as single polymorphisms showed no association with CMC1 osteoarthritis, a common haplotype C-A-C-T was identified that conferred an increased risk of 1.7 (95% CI, 1.1 to 2.7; \( p = 0.02 \)) for CMC1 osteoarthritis. For women, a higher risk of 2.1 (95% CI, 1.3 to 3.5; \( p = 0.004 \)) for CMC1 osteoarthritis was observed. However, this effect driven especially by female sex could not be determined owing to the small number of men in the GARP study. Furthermore, one other protective and rare haplotype was observed, which may imply that more relevant genetic variation of this locus is present which needs further investigation. Increasing the number of hSNPs could capture more relevant variation in the MATN3 region, not necessarily at the MATN3 gene itself.

Our results indicate that SNPs of the MATN3 gene, previously associated with idiopathic hand osteoarthritis, is also involved in spinal disc degeneration. In addition, a common haplotype at this locus, other than that carrying the T allele of SNP5, was found to be a moderate risk factor increasing susceptibility of CMC1 osteoarthritis. Together, our studies confirm the relevance of the MATN3 locus for spinal disc degeneration and CMC1 osteoarthritis. This needs replication in another osteoarthritis study group.

ACKNOWLEDGEMENTS

We thank all participants of the Rotterdam and GARP study. The Rotterdam Study is supported by the Erasmus Medical Centre and Erasmus University Rotterdam, the Netherlands Organisation for Scientific Research, the Netherlands Organisation for Health Research and Development, the Research Institute for Diseases in the Elderly, the Ministry of Education, Culture and Science, the Ministry of Health, Welfare and Sports, the European Commission (DG XII), and the Municipality of Rotterdam. The Leiden University Medical Centre, the Dutch Arthritis Association, and Pfizer Inc, Groton, Connecticut, USA support the GARP study. We further thank for the GARP study the support of the cooperating hospitals and referring rheumatologists, orthopaedic surgeons and general practitioners and for the Rotterdam study the support of general practitioners and pharmacists of the Ommoord district in Rotterdam. Finally, we thank Dennis Kremer and the Centre for Medical System Biology (CMSB) for their contribution to the genotyping of the SNPs.
